Raw local logarithmic slopes of Born-averaged D | primary $\mu = 10^{-8}$ state
beta=0 | deterministic baseline
beta=0.5
beta=1
beta=1.5
beta=2
beta=2.5
beta=3
$(D_2 - D_1)/\ln(L_2/L_1)$
Interval midpoint $\sqrt{L_1 L_2}$
Adjacent sizes within L=6–24
Reading the raw slopes
Look for a size interval consistent with a flat slope, within its errors.
Each panel has its own vertical scale.
Adjacent intervals share an endpoint: these slope estimates are correlated.
Lines connect finite differences; no plateau or common coefficient is fitted.
Error propagation uses independent size runs: $\mathrm{SE}_{\mathrm{slope}} = \sqrt{\mathrm{SE}_1^2 + \mathrm{SE}_2^2}/\ln(L_2/L_1)$.
Beta=0 is deterministic and has no Monte Carlo error bar; its size-dependent slope exposes finite-size curvature.
